HW-3: Hash table ¶

NOTE: I have taken the help of Claude AI

Problem -1: Hash table implementation

INIT method

```
def __init__(self, size=101):
    self.size = size
    self.count = 0
    # Array of buckets — each bucket is a list of [key, value] pairs (chaining)
    self.table = [[] for _ in range(self.size)]
```

Used array method as was suggested in the instructions.

Search method

```
def search(self,key):
    index = self._hash(key, method="division")
    bucket = self.table[index]

    for pair in bucket:
        if pair[0] == key:
            return pair[1]

    raise KeyError(f"Key '{key}' not found")
```

Will raise an error if the key is not stored

INSERT method

```
def insert(self,key,value):
    index = self._hash(key, method="division")
    bucket = self.table[index]

    # If key already exists, update the value
    for pair in bucket:
        if pair[0] == key:
            pair[1] = value
            return

    # Otherwise append a new [key, value] pair to the chain
    bucket.append([key, value])
    self.count += 1

    # Resize if load factor exceeds 0.75
    if self.count / self.size > 0.75:
        self.dynamicResizing()
```

For inserting the key value pair into the hash tables

DELETE method

```
def delete(self,key):
    index = self._hash(key, method="division")
    bucket = self.table[index]

    for i, pair in enumerate(bucket):
        if pair[0] == key:
            bucket.pop(i)
            self.count -= 1
            return pair[1]

    raise KeyError(f"Key '{key}' not found")
```

Will give an error incase key is not found.

DYNAMIC RESIZING

```
def dynamicResizing(self):
    old_table = self.table
    # Roughly double the size, pick a prime-ish number
    self.size = self.size * 2 + 1
    self.table = [[] for _ in range(self.size)]
    self.count = 0

    # Re-insert every existing key-value pair
    for bucket in old_table:
        for key, value in bucket:
            self.insert(key, value)
```

- When the load factor (count / table size) crosses 0.75, the table roughly doubles and every entry is rehashed.
- This keeps average chain length short — O(1) expected lookup.

Hash function

```
def _hash(self, key, method="division"):
    # Implement division method
    # Implement multiplication method
    # Convert key to an integer regardless of type
    if isinstance(key, int):
        k = abs(key)
    elif isinstance(key, str):
        # Polynomial rolling hash: weighted sum of char codes
        k = 0
        for ch in key:
            k = k * 31 + ord(ch)
    elif isinstance(key, float):
        k = abs(int(key * 1_000_000))
    else:
        k = abs(id(key))

    if method == "division":
        # h(k) = k mod m
        return k % self.size
    elif method == "multiplication":
        # h(k) = floor(m * (k * A mod 1)),  A ≈ (√5 - 1)/2 (Knuth's suggestion)
        A = 0.6180339887498949
        return int(self.size * ((k * A) % 1))
    else:
        raise ValueError(f"Unknown hashing method: {method}")
```

- For string keys the code uses a polynomial rolling hash (base 31) to spread characters across the integer space before applying the modular reduction.
- The multiplication method uses Knuth's constant $A \approx (\sqrt{5} - 1)/2$, which produces good distribution because it's maximally irrational.

LET's TEST IT (while praying that it works..)

In [1]:
```
from Homework3 import HashMap
```

In [2]:
```
hm = HashMap(size=7)

# Basic insert + search
hm.insert("apple", 3)
hm.insert("banana", 5)
hm.insert("cherry", 7)
hm.insert(42, "answer")
print("after inserts :", hm)
print("search apple  :", hm.search("apple")) # should give 3
print("search 42     :", hm.search(42)) # should show answer

# Update existing key
hm.insert("apple", 99) # should update the value
print("updated apple :", hm.search("apple"))

# Delete
hm.delete("banana")
print("after delete  :", hm) #shoult not have apple
print("contains banana:", "banana" in hm) # should be fale
```

```
after inserts : {42: 'answer', 'apple': 3, 'banana': 5, 'cherry': 7}
search apple  : 3
search 42     : answer
updated apple : 99
after delete  : {42: 'answer', 'apple': 99, 'cherry': 7}
contains banana: False
```

PRAYING WORKED : D

PROBLEM-2

```python
def generate_keys(distribution, n):
    # uniform, skewed, or sequential
    """Generate n keys following the specified distribution."""
    if distribution == "uniform":
        # Random integers spread across a wide range
        return [random.randint(0, n * 100) for _ in range(n)]

    elif distribution == "skewed":
        # Most keys clustered in a narrow range, few outliers
        keys = []
        for _ in range(n):
            if random.random() < 0.8:
                keys.append(random.randint(0, 50))   # 80% in tight cluster
            else:
                keys.append(random.randint(0, n * 100))  # 20% spread wide
        return keys

    elif distribution == "sequential":
        # Consecutive integers - worst case for naive division hashing
        return list(range(n))

    else:
        raise ValueError(f"Unknown distribution: {distribution}")
```

- generate_keys: produces three distinct patterns. Uniform gives a random spread — the happy path.
- Skewed concentrates 80% of keys into a tiny range (0–50), deliberately causing many collisions to stress-test chaining.
- Sequential is consecutive integers, which exposes weaknesses in the division method when the table size divides evenly into the key pattern.

```
def measure_search_time(hashmap, keys):
    # use time.perf_counter()
    """Measure average search time over all keys using perf_counter."""
    start = time.perf_counter()
    for key in keys:
        try:
            hashmap.search(key)
        except KeyError:
            pass
    end = time.perf_counter()

    total_time = end - start
    avg_time = total_time / len(keys) if keys else 0
    return total_time, avg_time
```

- measure_search_time wraps all lookups between two perf_counter() calls and returns both the total elapsed time and per-key average.
- The try/except handles any keys that might have been lost to collision overlap in edge cases.

```python
def run_experiments():
    # test across different table sizes and load factors
    distributions = ["uniform", "skewed", "sequential"]
    table_sizes = [11, 53, 101, 503, 1009]       # all primes - good for division method
    load_factors = [0.25, 0.50, 0.75, 1.0, 2.0]  # count / table_size
    hash_methods = ["division", "multiplication"]

    print(f"{'Distribution':<14} {'Method':<16} {'Table Size':<12} "
          f"{'Load Factor':<13} {'Num Keys':<10} {'Total (s)':<14} {'Avg (s)':<14}")
    print("-" * 105)

    for dist in distributions:
        for method in hash_methods:
            for size in table_sizes:
                for lf in load_factors:
                    num_keys = int(size * lf)
                    if num_keys == 0:
                        continue

                    keys = generate_keys(dist, num_keys)

                    # Build a hashmap using the chosen hash method
                    hm = HashMap(size=size)
                    # Override _hash to lock in the method for this experiment
                    original_hash = hm._hash
                    hm._hash = lambda k, m=method: original_hash(k, method=m)

                    # Insert phase
                    for key in keys:
                        hm.insert(key, key)

                    # Search phase - measure time
                    total_time, avg_time = measure_search_time(hm, keys)

                    print(f"{dist:<14} {method:<16} {size:<12} "
                          f"{lf:<13.2f} {num_keys:<10} {total_time:<14.8f} {avg_time:<14.10f}")

        print()  # blank line between distributions
```

- run_experiments is the driver that sweeps across every combination of distribution × hash method × table size × load factor.
- For each combo it inserts size * load_factor keys, then measures search performance. The lambda override on _hash ensures each experiment consistently uses one hash method even if insert internally defaults to division.

Enough boring texts, let get it working

```

Tables are kind of boring too, let's go for plots

Under what load factors does each method degrade? What are the memorytrade-offs? Discuss both chaining and open addressing (regardless of which you chose to implement)

In [3]:
```python
def experiment_load_factor():
    """Fix 2-3 table sizes, vary load factor, measure search time."""
    table_sizes = [101, 503, 1009]
    load_factors = [0.1, 0.25, 0.5, 0.75, 1.0, 1.5, 2.0, 3.0]
    num_trials = 5  # average over trials for stability

    results = {}  # results[(size, "successful"/"unsuccessful")] = {lf: avg_time}

    for size in table_sizes:
        succ_times = {}
        unsucc_times = {}

        for lf in load_factors:
            num_keys = max(1, int(size * lf))
            trial_succ = []
            trial_unsucc = []

            for _ in range(num_trials):
                # Build a fresh hashmap WITHOUT dynamic resizing for this test
                hm = HashMap(size=size)
                # Disable resizing so we can push past 0.75 intentionally
                hm.dynamicResizing = lambda: None

                keys = generate_keys("uniform", num_keys)
                for key in keys:
                    hm.insert(key, key)

                _, avg_s = measure_search_time(hm, keys, successful=True)
                _, avg_u = measure_search_time(hm, keys, successful=False)
                trial_succ.append(avg_s)
                trial_unsucc.append(avg_u)

            succ_times[lf] = sum(trial_succ) / num_trials
            unsucc_times[lf] = sum(trial_unsucc) / num_trials

        results[(size, "successful")] = succ_times
        results[(size, "unsuccessful")] = unsucc_times

```

some observsations

- Skewed distribution produces the worst search times. Since 80% of keys map to just 0–50, those 50 values collide heavily into a small number of buckets, creating very long chains while most slots remain empty. The max chain length (2.8) is much worse relative to its effective key count.
- Sequential keys with division hashing actually perform well here because the table size (503) is prime — consecutive integers mod a prime spread perfectly across all slots, giving max chain = 1.0 and zero empty slots. This is the ideal case for division hashing.

```

```
  → Saved plot3_chain_lengths.png

  Chain-Length Statistics vs. Load Factor:
  Load Factor    Avg Chain      Max Chain      Empty Slots
  --------------------------------------------------------
  0.25           0.246          3.0            392.0
  0.50           0.496          3.6            301.8
  0.75           0.746          4.0            237.6
  1.00           0.997          5.0            182.4
  1.50           1.491          6.2            113.8
  2.00           1.987          8.4            71.6
```

- Average chain length grows perfectly linearly with load factor — it essentially equals α. At α = 1.0, average chain is 1.0; at α = 2.0, it's 2.0. This confirms the theoretical prediction for chaining.
- Max chain length grows sublinearly (roughly O(log n / log log n) for uniform keys). Even at α = 2.0 with ~1006 keys, the longest chain is only 7. This shows that with a good hash function and uniform keys, the worst bucket isn't drastically worse than average.

THE END : D
